## Introduction

### 1.1 Networks

Several natural and artificial systems are composed of separate entities that interact together, forming networks - or, at least, they can be approximately modelled as networks. Often, these interactions generate complex behaviors, which would not exist without the interactions. For instance, neural circuits blabla.

A major area of research today is to understand precisely how this large-scale complex dynamics emerges from the interactions between units in networks. This ranges from setting up experiments XX, modelling to a high precision, and also building the basic theory that aims to describe the fundamental aspects of these networks. For this thesis we have focused on the latter case, aiming to study the fundamental behavior of simple, non-specific, networks. To do this, we have relied on a second layer of abstraction: often, networks can be modelled as dynamical systems following ODEs of the general form:

$$\dot{x}_i = f(x_i) + g(x) \tag{1.1}$$

where XX. Introduce topology, connections. Examples? power grids and neural networks and kuramoto?

This abstraction is quite helpful, because systems of this form can be studied using techniques from dynamical systems theory. XX?

Among the plethora of important dynamics arising in networks, we have in this thesis focused on three particular behaviors: malleability, multistability and metastability. Although separate, they are intrinsically related, as we will see. For the first two, we have focused on how they are controlled by the network's topology.

The first behavior we have studied is *dynamical malleability*, which refers to the capacity of a network to change its dynamics when the individual parameters of units or connections are changed. We studied this behavior in Kuramoto oscillator networks of the form

$$\dot{\theta} \dots \tag{1.2}$$

These networks serve as paradigmatic models to understand emergent behavior - in particular, synchronization - in complex networks. They can be derived as an approximation for generic coupled limit cycle oscillators under weak coupling [1]. Although it does not model a particular real-world system, it has been used as a simple model for large-scale brain networks [2] and power grids [3]. Originally used to describe chemical oscillations XX.

# Methodology

### 2.1 Fundamental (to us) aspects of dynamical systems theory

#### 2.1.1 Our dynamical systems and the uniqueness and existence of their solutions

In this thesis we study dynamical systems described by a state variable  $x = (x_1, x_2, \dots, x_n)^T \in M$ , where  $M \subseteq \mathbb{R}^n$  is the state space, and  $T$  denotes the transpose operation. The state variable is a point in this  $n$ -dimensional state space. In a continuous-time dynamical system, the state evolves according to the equation:

$$\dot{x}(t) = f(x(t)) \quad (2.1)$$

where  $f : M \rightarrow M$ . Systems obeying Eq. ?? are deterministic: there is no randomness, no stochasticity, no noise. This means that, starting from one single state at time  $t$ , we can in principle describe the whole past and future evolution of the system. Furthermore, there is a lack of an explicit time dependence in  $f$  - i.e.,  $\partial f_i / \partial t = 0$  for  $i = 1, \dots, n$ . In this case, the dynamical system is said to be autonomous.

To obtain solutions to system ?? we need to provide one state, which we typically call an initial condition  $x_0 = x(0) \in \mathbb{R}^n$ . The combination of  $\dot{x} = f(x)$  with  $x(0) = x_0$  defines an initial value problem. A fundamental theorem makes our lives studying this problem much easier. This is the theorem of existence and uniqueness of solutions. For  $x \in \mathbb{R}^n$  and  $f : \mathbb{R}^n \rightarrow \mathbb{R}^n$ , it requires that  $f$  is continuous and that all of its partial derivatives  $\frac{\partial f_i}{\partial x_j}$ , for  $i, j = 1 \dots n$  are continuous in some open connected set  $D \subset \mathbb{R}^n$ . This basically means that it requires our function  $f$  to be sufficiently smooth. Then, for initial conditions  $x_0 \in D$ , the initial value problem has a solution  $x(t)$  on some time interval  $(-\tau, \tau)$  about  $t = 0$ , and the solution is unique! [?]

In state space, each solution describes a trajectory, a path, that goes through its initial condition  $x_0$ . The uniqueness of solutions implies that, within this time interval  $(-\tau, \tau)$ , different trajectories do not intersect in state space. This is a crucial property underlying all systems we study.

A useful notation for the evolution of a continuous dynamical system is through the evolution operator  $\Phi^t(x)$ , which, informally defined, evolves the point  $x$  forward  $t$  time units. That is,  $\Phi^t(x(0)) = x(t)$ .

#### 2.1.2 The fate of linear dynamical systems

Although trajectories do not cross, they can share the same fate, meaning they can converge to the region in state space. We can introduce this notion with a very simple mathematical example of a linear system. It has the form

$$\dot{x}(t) = Ax(t) \quad (2.2)$$

where  $A$  is a constant  $(n \times n)$  matrix.

If the eigenvalues  $\lambda_i \in \mathbb{C}$  of  $A$  are all unique, its eigenvectors  $v_i \in \mathbb{R}^n$  are linearly independent. Then, the general solution to this system can be written as [?]:

$$x(t) = \sum_{i=1}^n C_i e^{\lambda_i t} v_i \quad (2.3)$$

Then, each initial condition determines the constant coefficients  $C_i \in \mathbb{R}$ . From Eq. ?? we can already notice that the origin of the system,  $o = (0, \dots, 0)^T$ , is a solution. If all the eigenvalues are negative, then all trajectories in state space converge to this point as  $t \rightarrow \infty$ . In this case, the origin is said to be an attracting solution, or an attractor. Thus, although trajectories in this system do not intersect, they all converge to the origin as  $t \rightarrow \infty$ , so as time passes they all behave like the origin. This origin itself has no dynamics: the trajectory starting at the origin does not move. For this reason we say that the origin, the attractor in this system, is invariant: the set  $\{o\}$  flows onto itself. If we were to plot the position of this trajectory over time, we would get a constant line, in a steady state. For this reason, this type of attractor is called an equilibrium.

Although the ultimate fate of linear systems is kind of boring, the journey before the end is more interesting. The path trajectories take while converging to the attractor is called a transient. The transient dynamics of linear systems is dictated by the constellation of eigenvalues  $\lambda_i$ . For more details, the reader can refer to standard books on linear/nonlinear dynamics, such as Ref. [?].

### 2.1.3 The fate of nonlinear dynamical systems I: attractors

Linear system are monostable: they can have only one attractor. If we now move to nonlinear systems, the situation is different. Now, trajectories can have multiple distinct fates, multiple attractors. To which attractor a trajectory goes to depends on where it starts. In a multistable system, the state space is then divided into distinct regions, wherein trajectories starting on each region go to their corresponding attractor. A simple and intuitive example is that of a ball on a certain landscape with hills and valleys. The ball of course rolls downhill and, due to friction, it eventually stops at one of the valleys.

Nonlinear systems can also have different types of attractors. In the linear system with negative eigenvalues, the only attractor was an equilibrium, a point, at the origin. But attractors can be extended structures in state space, including more than a single point. Figure XX shows examples of other types of attractors. These include a closed curve, wherein trajectories revolve around, and repeat after some time  $T > 0$ . If this closed curve attracts trajectories, it is called a limit cycle. Another type of attractor is a torus. XX. Also Chaos.

Given now these examples, let us now define the terms we have used a bit more properly.

### 2.1.4 Formalizing attractors and basins

We have just presented examples of attractors, sets of points in state space to which trajectories eventually converge, and their basins of attraction, the regions containing those converging trajectories. Since in this thesis we will deal a lot with these concepts, we provide now an attempt at formalizing. The idea is to have the concepts clear in mind for later. In practice, we will only use the informal definition we just gave. In particular, the definition of attractor can vary considerably in the literature. Without attempting to claim any superiority, we attempt here to provide a definition that suits our studies.

First, we define an omega limit set  $\omega(x)$  of a point  $x_0 \in M$  as [?]:

$$\omega(x_0) = \{x : \forall T \forall \epsilon > 0 \text{ there exists } t > T \text{ such that } |f(x_0, t) - x| < \epsilon\}. \quad (2.4)$$

Consider a point  $x \in \omega(x_0)$  in the  $\omega$  limit set of  $x_0$ . Then, by definition, a trajectory that passes through  $x_0$  comes arbitrarily close to  $x$  infinitely often as  $t$  increases.

From this, we can define the *basin of attraction* of a set  $A$  as  $\mathcal{B}(A) = \{x \in M : \omega(x) \subset A\}$ . This only looks at the long-term behavior of trajectories; the transient dynamics could be anything, including the case that trajectories go very far from  $A$ , as long as they go back to it and stay there eventually.

Now to define an attractor, we first define a weaker (or, on the more optimistic side, a more general) version, called the *Milnor attractor*. It is a useful concept when dealing with metastability. A set  $A$  is a Milnor attractor if:

1. Its basin of attraction  $\mathcal{B}(A)$  has strictly positive measure (i.e., if  $m(\mathcal{B}(A)) > 0$ ), where  $m(S)$  denotes a measure equivalent to the Lebesgue measure of set  $S$  [?]. This condition says that there is some probability that a randomly chosen point will be attracted to  $A$  [?].
2. For any closed proper subset  $A' \subset A$ , the set difference  $\mathcal{B}(A) \setminus \mathcal{B}(A')$  also has strictly positive measure. This ensures that every part of  $A$  plays an essential role - one cannot decompose  $A$  into an attracting part and another part that does not attract [?, ?]. A closed set here means that it contains all its limit points. And proper means its non-empty.

Furthermore, the Milnor attractor does not have to attract all the points in its neighborhood, and there can also be orbits that transiently go very far from the attractor, even if initially close, before eventually getting close to it. Further, it can in principle be composed into the union of two smaller Milnor attractors. To avoid these cases, we call a set  $A$  an *attractor* if

1.  $A$  is a Milnor attractor.
2.  $A$  contains an orbit that is dense in  $A$ . Basically, this means that there is an orbit in  $A$  that passes arbitrarily close to every point in  $A$ . This condition ensures that the attractor is not the union of two smaller attracting sets [?].
3. There are arbitrarily small neighborhoods  $U$  of  $A$  such that  $\forall x \in U$  one has  $\Phi^t(x) \subset U \forall t > 0$  and such that  $\forall y \in U$  one has  $\omega(y) \subset \omega(x)$ . That is, there are arbitrarily small neighborhoods around the attractor in which points inside stay inside and converge to  $A$ . This criterion is given in Ref. [?].

## 2.1.5 Invariant manifolds: structures that organize state space

In Sec. ?? we only considered the case when all the eigenvalues of the matrix  $A$  in the linear system  $\dot{x} = Ax$  were positive. If one eigenvalue  $\lambda_k$  is positive, then trajectories will diverge to infinity following the corresponding eigenvector  $v_k$ . When some eigenvalues are positive, and some are negative, the origin is a saddle-point. If all eigenvalues are positive, it is called a repeller. Figure ?? shows examples of equilibria in 2D linear systems. Note that typical trajectories approach the saddle-point along the  $y$ -axis and then diverge along the  $x$ -axis. That is, for  $t \rightarrow -\infty$ , trajectories converge to the  $y$ -axis and for  $t \rightarrow \infty$  they converge to the  $x$ -axis. The  $y$ -axis is called the stable manifold  $\mathbb{W}^s(o)$  of the origin  $o$  and the  $x$ -axis is the unstable manifold  $\mathbb{W}^u(o)$  of the origin. We can define these manifolds

$$\mathbb{W}^s(o) = \{x \in M : \Phi^t(x) \rightarrow o \text{ as } t \rightarrow \infty\}, \quad \mathbb{W}^u(o) = \{x \in M : \Phi^t(x) \rightarrow o \text{ as } t \rightarrow -\infty\}. \quad (2.5)$$

Let us separate the eigenvectors  $v_i$  into two parts: the ones with negative eigenvalues  $v_1^-, \dots, v_{n_s}^-$  and the ones with positive eigenvalues  $v_1^+, \dots, v_{n_u}^+$ . Then we can define the stable and unstable subspaces, respectively, as

$$\mathbb{E}^s = \text{span}(v_1^-, \dots, v_{n_s}^-) \quad \mathbb{E}^u = \text{span}(v_1^+, \dots, v_{n_u}^+) \quad (2.6)$$

For a linear system, the stable manifold of the origin coincides with the stable space  $\mathbb{E}^s$  and the unstable manifold coincides with the unstable space. In general, as in the example of the saddle-point, these manifolds act to organize the behavior of trajectories in state space.

These concepts can be extended for nonlinear systems. To do this, the first step is to think about the linearization of the nonlinear system. Suppose our nonlinear system of interest has

an equilibrium  $x^* \in M$ . It turns out that the behavior sufficiently close to this equilibrium is linear, despite the system globally being nonlinear [?, ?]! To see this, we first move the origin of our system to  $x^*$  by defining a new variable  $y(t) = x(t) - x^*$ . Then,

$$\dot{y} = \dot{x} = f(y + x^*) \equiv g(y) \quad (2.7)$$

where we define a convenience function  $g(y)$ . Expanding  $g(y)$  around  $y = 0$  (i.e., around the equilibrium  $x(t) = x^*$ ) gives us

$$\dot{y} = g(0) + J_g(0)y + \mathcal{O}(y^2), \quad (2.8)$$

where  $J_g(y) = \frac{\partial g_i(y)}{\partial y_j}$  is the Jacobian of  $g$ . It is related to the Jacobian of  $f$  by  $J_g(y) = J_f(x)$ , so  $J_g(y = 0) = J_f(x = x^*)$ . Since  $g(0) = f(x^*) = 0$ , then if we are sufficiently close to the origin we can also ignore the terms  $\mathcal{O}(y^2)$  and therefore we get

$$\dot{y} = J_g(0)y. \quad (2.9)$$

That is, the behavior of the nonlinear system sufficiently close to the equilibrium is linear, with the constant matrix function being the Jacobian evaluated at the equilibrium!

But the good news don't stop here! There is the Hartman-Grobman theorem, which basically shows that the state space near a hyperbolic equilibrium to the state space of the linearization. An equilibrium is hyperbolic if the eigenvalues of the Jacobian evaluated on it are all nonzero, i.e., if  $\lambda_i \neq 0 \forall i = 1, \dots, n$ . Topologically equivalent means that the linearized state space and the local state space near the equilibrium are distorted versions of each other. They can be bended and warped, but not ripped. In particular, closed orbits have to remain closed, and connections between saddle points have to remain [?]. Mathematically, topologically equivalent means there is a homeomorphism (continuous deformation with continuous inverse) from one state space into the other; trajectories can be mapped from one to the other, and the direction of time is the same [?].

Stating the theorem more formally, suppose a hyperbolic equilibrium  $x^* \in M$  such that  $f(x^*) = 0$  and such that all its eigenvalues are nonzero. Then, there is a neighborhood  $N$  of  $x^*$  and a homeomorphism  $h : N \rightarrow M$  such that [?]

- $h(x^*) = 0$
- the flow  $\dot{x} = f(x)$  in  $N$  is topologically conjugate to the flow of the linearization  $\dot{y} = Ay$  by the continuous map  $y = h(x)$ . Topologically conjugate basically meaning a change of coordinates in a topological sense.

This guarantees that the stability of the equilibrium is the same in both cases, so we can use the linearization to gain important insights about the stability of equilibria in the nonlinear system!

What about the stable and unstable manifolds? In analogy to the linear case, we can define local stable and unstable sets near a neighborhood  $U$  of an equilibrium  $x^*$  for the nonlinear system [?]:

$$\mathbb{W}_{\text{loc}}^s(x^*) = \{x \in M : \Phi^t(x) \rightarrow o \text{ as } t \rightarrow +\infty \text{ and } \Phi^t(x) \in U \forall t \geq 0\}, \quad (2.10)$$

$$\mathbb{W}_{\text{loc}}^u(x^*) = \{x \in M : \Phi^t(x) \rightarrow o \text{ as } t \rightarrow -\infty \text{ and } \Phi^t(x) \in U \forall t \leq 0\}. \quad (2.11)$$

Herein comes the stable manifold theorem. It states that, for a hyperbolic equilibrium  $x^*$ :

- The local stable set  $\mathbb{W}_{\text{loc}}^s(x^*)$  is a smooth manifold whose tangent space has the same dimension  $n_s$  as the stable space  $\mathbb{E}^s$  of the linearization of  $f$  at  $x^*$ .  $\mathbb{W}_{\text{loc}}^s(x^*)$  is also tangent to  $\mathbb{E}^s$  at  $x^*$ .
- The local unstable set  $\mathbb{W}_{\text{loc}}^u(x^*)$  is a smooth manifold whose tangent space has the same dimension  $n_u$  as the unstable space  $\mathbb{E}^u$  of the linearization of  $f$  at  $x^*$ .  $\mathbb{W}_{\text{loc}}^u(x^*)$  is also tangent to  $\mathbb{E}^u$  at  $x^*$ .

The homeomorphism guaranteed by the Hartman-Grobman theorem maps  $\mathbb{W}_{\text{loc}}^s(x^*)$  into  $\mathbb{E}^s$  and  $\mathbb{W}_{\text{loc}}^u(x^*)$  into  $\mathbb{E}^u$  one-to-one, as shown in Fig. XX. Further, the stable manifold theorem that  $\mathbb{E}^s$  and  $\mathbb{E}^u$  actually approximate the local manifolds  $\mathbb{W}_{\text{loc}}^s(x^*)$  and  $\mathbb{W}_{\text{loc}}^u(x^*)$ , respectively [?]. As a consequence, we get the behavior in Fig. XX. (fig 6.2.4 do argyris)

The manifolds we just looked at are defined for a local neighborhood  $U$  around the equilibrium. We can extend them towards the whole of state space by defining global manifolds as:

$$\mathbb{W}^s(x^*) = \bigcup_{t \leq 0} \Phi^t(\mathbb{W}_{\text{loc}}^s(x^*)) \quad (2.12)$$

$$\mathbb{W}^u(x^*) = \bigcup_{t \geq 0} \Phi^t(\mathbb{W}_{\text{loc}}^u(x^*)) \quad (2.13)$$

That is, the global stable manifold is obtained by integrating the local stable manifold backwards, looking at where the trajectories on it came from. For the unstable manifold, we integrate the local unstable manifold forwards, to see where it goes to. As mentioned before, these manifolds usually play a big role in organizing state space. The next section briefly shows how stable manifolds of unstable equilibria can act as the boundary separating two basins of attraction.
